Abstract

It is widely believed that order of exactness is a good measure of the quality of an algorithm for numerical quadrature. We show that this is not the case, by exhibiting a situation in which the optimal algorithm does not even integrate constants exactly. We also show that there are situations in which the penalty for using equidistant nodes is unbounded. Finally, we show that the complexity of obtaining an \( \varepsilon \)-approximation can be an arbitrary function of \( \varepsilon \), i.e., there is no hardest quadrature problem.
1. **Introduction**

In this Introduction, we use terms such as "algorithm," "information," "optimal," etc. without definition. They are rigorously defined in Section 2.

We consider the quadrature problem, and ask the following questions:

1. What is the relation between order of exactness and optimality of an algorithm?
2. Are equidistant or roughly-equidistant nodes nearly optimal?
3. If $\text{comp}(\varepsilon)$ denotes the complexity of finding an $\varepsilon$-approximation, what kind of function can $\text{comp}$ be?

We show the following:

1. There is no relation between order of exactness and optimality.
2. The penalty for using (roughly-) equidistant nodes can be unbounded.
3. The complexity, $\text{comp}(\varepsilon)$, can be (almost) any non-decreasing function of $\varepsilon$ such that $\lim_{\varepsilon \to 0} \text{comp}(\varepsilon) = +\infty$.

In the remainder of this Introduction, we briefly discuss each of these issues in turn, citing the evidence that led us to ask these questions.
(1.) **Order of exactness and optimality.** Many people believe that maximizing the order of exactness of a quadrature rule (i.e., having it exactly integrate polynomials of as high a degree as possible) is one of the good ways to choose a quadrature rule, as may be seen by reading the chapter on quadrature in almost any numerical analysis textbook. (When the nodes are equally spaced, this leads to Newton-Cotes rules; when they are allowed to vary, this yields Gaussian rules.)

Furthermore, the literature abounds with situations in which some exactness condition is either imposed a priori or is necessary. As an example, suppose the integrand has \( r \geq 1 \) \( L_2 \)-derivatives, the \( r \)th being given an a-priori \( L_2 \)-bound. The Sard theory [8] only considers linear algorithms which are exact for polynomials of degree \( r - 1 \). However, this exactness condition need not be stated as an assumption. It can be derived from the facts that any homogeneous algorithm with finite error must integrate polynomials of degree \( r - 1 \) exactly, and that linear optimal algorithms exist, see [10, Chapter 3].

On the other hand, Motornyj [6] has shown that the rectangle rule (which is exact only for constants) is optimal for integrating periodic functions with \( r \geq 1 \) \( L_\infty \)-derivatives. Hence, there is no general relation between the smoothness of
the integrand and the degree of exactness of the optimal rule. However, it may be shown that for this class of integrands, any homogeneous algorithm with finite error must integrate constants exactly.

Hence we see that in the examples presented above, any homogeneous algorithm must integrate constants exactly if it is to have finite error. Is this true in general?

In Section 3, we show that the answer to this problem is negative. In fact, we show an even stronger result. We construct classes of integrands for which the optimal algorithm does not integrate constants exactly, yet the nth optimal algorithm has finite error which is $O(n^{-1})$ as $n \to \infty$. Hence this algorithm provides a strong negative counterexample: it is not exact for constants, yet is optimal, has finite error, and is convergent.

Hence, there is no basic connection between order of exactness on the one hand, and finite error, convergence, or optimality on the other.

*In this paper, we use the classical $O$-notation, as well as $\Omega$- and $\Theta$-notation. If $f$ and $g$ are functions, then

\[ f = \Omega(g) \quad \text{iff} \quad g = O(f) \]

and

\[ f = \Theta(g) \quad \text{iff} \quad f = O(g) \text{ and } g = O(f). \]
(2.) *Are roughly-equidistant nodes close to optimal?*

In all of the many classes of integrands considered in [10], roughly-equidistant nodes were (to within a constant) optimal points of evaluation for the integrand. Moreover, it is shown in [4] that equidistant nodes were optimal for the problem of integrating functions whose total variation was a priori bounded.

In this true in general, i.e., are roughly-equidistant nodes always almost-optimal? One reason to believe that this might be so is based on the fact that (as long as class of integrands is balanced and convex) an adaptive choice of nodes is never better than a nonadaptive choice, see [10, Chapter 2.6]. Hence, there appears to be no reason to do extra evaluations in some "critical" subinterval, since letting the points of evaluation depend on the integrand is no better than having them independent of the integrand. That is, it would be reasonable to expect that the points of evaluation should be more-or-less evenly distributed throughout the interval; that is, it should suffice to consider nodes which are roughly equidistant.

In Section 4, we show that this is not the case. We construct a class of integrands, as well as an optimal choice of evaluation points for that class which are not equidistant.
Moreover, we show that the penalty for using roughly-equidistant nodes is unbounded.

(3.) Is there a hardest quadrature problem? Bakhvalov has shown that for any \( \alpha > 0 \), there is a class of integrands for which the \( \varepsilon \)-complexity of quadrature is \( \mathcal{O}(\varepsilon^{-2}) \) as \( \varepsilon \to 0 \). Is this the worst behavior for the \( \varepsilon \)-complexity? If not, is there a worst \( \varepsilon \)-complexity function, which would correspond to a hardest quadrature problem? In Section 5, we show that the answer is negative. In fact, the nth minimal error can go to zero arbitrarily slowly: for any "reasonable" function \( \psi \) for which \( \psi(0) = 0 \) and \( \psi \) is monotone increasing, there is a class of integrands for which the nth minimal error is \( \mathcal{O}(\psi(\frac{1}{n})) \) as \( n \to \infty \). This is used to show that the \( \varepsilon \)-complexity can be almost any nondecreasing function of \( \varepsilon \) such that
\[
\lim_{\varepsilon \to 0} \text{comp}(\varepsilon) = +\infty.
\]
2. Preliminary concepts.

In this Section, we define the terminology used in the Introduction, and introduce some results from [10].

Let $F$ be a balanced, convex subset of the Riemann-integrable functions on $[0,1]$. We wish to approximate the solution operator $S : F \to \mathbb{R}$ given by

$$Sf := \int_0^1 f(t)dt \quad \forall f \in F.$$  \hspace{1cm} (2.1)

In what follows, we often refer to the problem $(S,F)$. We suppose that all we know about an integrand is its values at a finite number of points in the interval. Hence, given a grid

$$\Delta := \{0 \leq t_1 < t_2 < \ldots < t_n \leq 1\},$$  \hspace{1.5cm} (2.2)

we only know the information

$$N_\Delta f := [f(t_1), \ldots, f(t_n)] \quad \forall f \in F.$$  \hspace{1cm} (2.3)

of cardinality $n$. An algorithm using this information is any mapping $\gamma : N_\Delta (F) \to \mathbb{R}$; the class of all such algorithms is denoted by $\Gamma(N_\Delta, F)$. The (worst-case) error of an algorithm $\gamma$ is defined to be

$$e(\gamma, F) := \sup_{f \in F} |Sf - \gamma(N_\Delta f)|.$$  \hspace{1cm} (2.4)

We wish to find, for each information operator $N_\Delta : F \to \mathbb{R}^n$,
the best algorithm possible, i.e., the one with smallest error. Let

\[ e(N_\Delta, F) := \inf \{ e(\omega) : \omega \in \mathcal{F}(N_\Delta, F) \} \]

denote the optimal error from \( \mathcal{F}(N_\Delta, F) \), i.e., the smallest error among all algorithms using \( N_\Delta \). Then results from [10] yield that

\[ e(N_\Delta, F) = \sup \{|Sz| : z \in F \cap \ker N_\Delta \} \]

Moreover, Smolyak's lemma [3,10] tells us that there exist coefficients \( \alpha_1, \ldots, \alpha_n \in \mathbb{R} \) such that

\[ e(\mathcal{F}^*, F) = e(N_\Delta, F) \]

where \( \mathcal{F}^* \) is the algorithm

\[ \mathcal{F}^*(N_{\Delta}) := \sum_{i=1}^{n} \alpha_i f(t_i) \quad \forall f \in F. \]

That is, there always exists a linear optimal error algorithm for \( F \) using \( N_\Delta \).

Next, we wish to choose, for any positive integer \( n \), the best possible information of cardinality \( n \). From (2.5), we see that this may be done as follows. Let

\[ e(n, F) := \inf_{\Delta} e(N_\Delta, F) \]

(the infimum being over all \( \Delta \) satisfying (2.2)) be the \( n \)-th
minimal error. If there is a grid $\Delta^*$ satisfying (2.2) such that

\[(2.10) \quad e(N_{\Delta^*}, F) = e(n, F),\]

then $N_{\Delta^*}$ is an $n$-th optimal information operator. Let $\mathfrak{F}_n(F)$ denote the class of all algorithms using information of cardinality $n$. If $\gamma^*$ is an optimal error algorithm using the n-th optimal information $N_{\Delta^*}$, then

\[(2.11) \quad e(\gamma^*, F) \leq e(\gamma, F) \quad \forall \gamma \in \mathfrak{F}_n(F).\]

Hence, $\gamma^*$ is an $n$-th minimal error algorithm.

Finally, we come to the notion of problem complexity, under the model of computation introduced in [10]. (The main features of this model are that each arithmetic operation has unit cost, and that evaluating any $f \in F$ at any point in $[0,1]$ has fixed finite cost $c$; we generally expect $c \gg 1$ in practice.)

Let $\varepsilon > 0$ be a given error criterion. We define the problem complexity

\[(2.12) \quad \text{comp}(\varepsilon, F) := \inf\{\text{comp}(\gamma) : e(\gamma, F) \leq \varepsilon\},\]

$\text{comp}(\gamma)$ denoting the complexity of the algorithm $\gamma$. That is, the problem complexity is the infimum of the complexities of all algorithms whose error does not exceed $\varepsilon$. Results from [10] yield that
(2.13) \[ \text{comp}(\varepsilon, F) = (c+a)m(\varepsilon, F) - 1, \]

where \( a \in [1, 2] \) and the \( \varepsilon \)-cardinality number \( m(\varepsilon, F) \) is given by

(2.14) \[ m(\varepsilon, F) := \inf \{ n \in \mathbb{Z} : e(n, F) \leq \varepsilon \}. \]

Roughly speaking, the \( \varepsilon \)-cardinality number is the functional inverse of the \( n \)-th minimal error. Since \( c \gg 1 \), (2.13) and (2.14) imply (roughly speaking) that

(2.15) \[ \text{comp}(\varepsilon, F) \approx c e^{-1}(\varepsilon). \]

Moreover, the linear optimal error algorithm using \( n \)-th optimal information (where \( n = m(\varepsilon, F) \)) is (roughly speaking) an optimal complexity algorithm for solving the problem with error \( \varepsilon \), since this algorithm has complexity at most \( (c+2)m(\varepsilon, F) - 1 \).
3. **Exactness for constants is unnecessary.**

In this Section, we show that a finite-error algorithm need not integrate constants exactly. This is done by showing an even stronger result: we construct a class of integrands for which the n-th minimal-error algorithm is not exact for constants, yet has error which is $\mathcal{O}(n^{-1})$ as $n \to \infty$.

To do this, we choose $r \in (0,1)$, define $\phi : [0,1] \to \mathbb{R}$ by

$$
\phi(t) := t^r \quad (0 \leq t \leq 1),
$$

and let

$$
G := \{ g \in \mathcal{W}^1,\infty(0,1) : g(0) = 0 \text{ and } \| g' \| \leq 1 \},
$$

where $\mathcal{W}^1,\infty(0,1)$ is (as usual) the space of absolutely continuous $g$ such that $g' \in L_\infty(0,1)$ and $\| \cdot \|$ is the $L_\infty(0,1)$-norm. Then we take

$$
F := \{ f : [0,1] \to \mathbb{R} | Rf \in G \}
$$

as our class of integrands, where

$$
(Rf)(x) := \frac{f(\phi^{-1}(x))}{\phi'(\psi^{-1}(x))} = \frac{f(\phi^{-1}(x))(\phi^{-1})'(x)}{\phi'(\phi^{-1}(x))} = \frac{1}{r} x^{1/r-1}.
$$

Using the change of variables $t = \phi^{-1}(x)$, we have
\[ (3.5) \quad Sf = \int_0^1 f(t)dt = \int_0^1 (Rf)(x)dx = SRf \quad \forall f \in F. \]

Hence, every element of \( F \) is Riemann-integrable. Moreover, \( F \) contains nonzero constants.

As we will see below, the problem \( (S,G) \) is easy to analyze. However, we are more interested in the problem \( (S,F) \), since we will be able to construct optimal error algorithms for this problem which do not integrate constants exactly. Hence, we need to investigate the relations between these two problems.

We first consider information for the problem \( (S,F) \). Since there exist \( f \in F \) such that \( f(0) \) is infinite, we only consider information of the form

\[ (3.6) \quad \Delta f := [f(t_1) \ldots f(t_n)] \quad \forall f \in F, \]

where

\[ (3.7) \quad \Delta := \{0 < t_1 < \ldots < t_n \leq 1\}. \]

For convenience, we let \( t_0 := 0 \) and \( t_{n+1} := 1 \); of course, \( t_n = t_{n+1} \) when \( t_n = 1 \).

Next, we consider information for the problem \( (S,G) \). Since \( g(0) = 0 \) for any \( g \in G \), we only consider information of the form

\[ (3.8) \quad \Delta g := [g(x_1) \ldots g(x_n)] \quad \forall g \in G, \]
where

\begin{equation}
\tilde{\varepsilon} := \{0 < x_1 < \ldots < x_n \leq 1\}.
\end{equation}

We let \( x_0 := 0 \) and \( x_{n+1} := 1 \).

The relation between the two problems is given in

**Lemma 3.1:** For information \( N_\varepsilon \) for the problem \((S,F)\) given by (3.6)-(3.7), let \( N_\varepsilon \) be the information for the problem \((S,G)\) given by (3.8)-(3.9) with

\begin{equation}
x_i := \psi(t_i) \quad (1 \leq i \leq n).
\end{equation}

(i) If

\begin{equation}
\psi_\varepsilon(N_\varepsilon G) := \Sigma_{i=1}^n \alpha_i g(x_i) \quad \forall g \in G
\end{equation}

is a linear optimal error algorithm for \( G \) using \( N_\varepsilon \), then

\begin{equation}
\psi_\varepsilon(N_\varepsilon F) := \Sigma_{i=1}^n \frac{\alpha_i}{\psi'(t_i)} f(t_i) \quad \forall f \in F
\end{equation}

is a linear optimal error algorithm for \( F \) using \( N_\varepsilon \), and

\begin{equation}
e(\psi_\varepsilon,F) = e(N_\varepsilon,F) = e(N_\varepsilon,G) = e(\psi_\varepsilon,G).
\end{equation}

(ii) The \( n \)-th minimal errors for the problems \((S,F)\) and \((S,G)\) are the same:

\[ e(n,F) = e(n,G). \]
Moreover, \( N_\Delta \) is \( n \)-th optimal information for \((S,F)\) iff \( N_\Delta \) is \( n \)-th 'optimal information for \((S,G)\).

Proof: It suffices to prove (i), since (ii) follows immediately from (3.13). To show (i), let \( f \in F \) and set \( g := Rf \). Then
\[
(3.5) \quad Y_i \in \mathcal{D}(N_\Delta f) = \mathcal{D}(N_\Delta g).
\]
Hence \( e(\mathcal{D}_\Delta F) = e(\mathcal{D}_\Delta G) \) by (2.4). Since \( \mathcal{D}_\Delta \) is an optimal error algorithm for \( G \) using \( N_\Delta \), \( e(\mathcal{D}_\Delta ,G) = e(N_\Delta ,G) \).
Finally, \( e(N_\Delta ,G) = e(N_\Delta ,F) \) by (2.6) and (3.5). □

We are now able to exhibit a linear optimal error algorithm \( \mathcal{D}_\Delta \in \mathcal{S}(N_\Delta ,F) \). To do this, choose \( \tilde{\mathcal{D}} \) as in Lemma 3.1 and define a space \( L(\tilde{\mathcal{D}}) \) of piecewise linear polynomials by
\[
(3.14) \quad L(\tilde{\mathcal{D}}) := \{ g \in L^1,\infty(0,1) : g(0) = 0, g(x_n) = g(1),
\]
\[
g(x) = \frac{i}{i+1}x + \frac{1}{i+1} \text{ on } [x_i,x_{i+1}] \text{ (0 \leq i \leq n)} \}.
\]
Let \( \{s_1,\ldots,s_n\} \) be the basis of \( L(\tilde{\mathcal{D}}) \) for which
\[
(3.15) \quad s_i(x_j) = \begin{cases} 1 & \text{if } j = i \text{ and } 1 \leq i \leq n+1 \\ 0 & \text{otherwise} \end{cases},
\]
and set
\[
s_n(x_n) = s_n(1) = 1
\]
(3.16) \( \beta_i := \frac{1}{r} t_i^{1-r} \int_0^1 s_i(x) \, dx \quad (1 \leq i \leq n). \)

We then define

(3.17) \( \varphi_{\Delta} (N f) := \sum_{i=1}^{n} \beta_i f(t_i). \)

**Theorem 3.1:**

(i) \( \varphi_{\Delta} \) is a linear optimal error algorithm for \( F \) using \( N_{\Delta} \).

(ii) Let

\[ e_{\Delta} := x_{i+1} - x_i \quad (0 \leq i \leq n). \]

Then

(3.18) \( e(\varphi_{\Delta}, F) = e(N_{\Delta}, F) = e(N_{\Delta}, G) = \frac{1}{4} \sum_{i=0}^{n-1} \frac{2}{5} x_i + \frac{1}{2} \frac{2}{5} n. \)

**Proof:** (i) For \( g \in G \), we define the interpolant \( P_{\Delta} g \in L(\Delta) \) by

(3.19) \( (P_{\Delta} g)(x) := \sum_{i=1}^{n} g(x_i) s_i(x). \)

Then (3.11) and (3.16) yield

(3.20) \( \varphi_{\Delta} (N_{\Delta} g) = SP_{\Delta} g. \)

Following the techniques of [9, pp. 30-31], we see that \( \varphi_{\Delta} \) is a linear optimal error algorithm for \( G \) using \( N_{\Delta} \). Hence, Lemma 3.1 yields that \( \varphi_{\Delta} \) is a linear optimal error algorithm for \( F \) using \( N_{\Delta} \).

(ii) It suffices to prove the last equality. Define
(3.21) \[ z_{\Delta}(x) := \begin{cases} x - x_i & \text{for } x \in [x_i, \frac{1}{2}(x_i + x_{i+1})], \quad 0 \leq i \leq n \\ x_{i+1} - x & \text{for } x \in \left[\frac{1}{2}(x_i + x_{i+1}), x_{i+1}\right], \quad 0 \leq i \leq n \\ x - x_n & \text{for } x \in [x_n, 1] \end{cases} \]

As in [9, pp. 55-57, we see that

(3.22) \[ e(N_{\Delta}, G) = Sz_{\Delta}. \]

A short calculation yields

(3.23) \[ Sz_{\Delta} = \frac{1}{4} \sum_{i=0}^{n-1} 2^{i + \frac{1}{2}}, \]

The result follows from (3.22) and (3.23). \[ \square \]

Remark 3.1: The proof of Theorem 3.1 establishes an even stronger result. An algorithm is a strongly optimal error algorithm if it produces a best possible approximation to \( S_f \) for every \( f \in F \) (rather than for just a worst-case \( f \in F \)). Since \( \varphi_\Delta \) is a strongly optimal error algorithm for \( G \) using \( N_\Delta \), we find that \( \varphi_\Delta \) is a strongly optimal error algorithm for \( F \) using \( N_\Delta \). \[ \square \]

We now show that for \( r \in (\frac{1}{2}, 1) \), the optimal error algorithm \( \varphi_{\Delta} \in \gamma(N_{\Delta}, F) \) has no "order of exactness," i.e., it does not even integrate (nonzero) constants exactly.

Theorem 3.2: Suppose that \( r \in \left(\frac{1}{2}, 1\right) \). Let \( |c| \leq \frac{r^2}{|1-r|} \), so that the constant function \( f: [0,1] \to \mathbb{R} \) given by
\[ f(t) := c \quad (0 \leq t \leq 1) \]

belongs to \( F \). Then

\[ \text{sgn}(Sf - \varphi_{\Delta}(Nf)) = \text{sgn} \ c. \]

Hence, \( \varphi_{\Delta} \) does not integrate nonzero constants exactly.

**Proof:** If \( c = 0 \), then linearity of \( \varphi_{\Delta} \) yields

\[ \varphi_{\Delta}(Nf) = 0 = Sf. \]

We now consider the case \( c > 0 \). Let \( g = Rf \), i.e.,

\[ g(x) = \frac{c}{r} x^{1/r-1}. \]

Then \( r \in \left( \frac{1}{2}, 1 \right) \) implies that \( g \) is monotone increasing and strictly concave on \([0,1]\). Hence

\[ g(x) > (P_{\Delta}g)(x) \quad \text{a.e.} \quad x \in [0,1]. \]

So (3.5), (3.10)-(3.12), and (3.20) yield

\[ Sf - \varphi_{\Delta}(Nf) = Sg - SP_{\Delta}g > 0, \]

as required.

Finally, when \( c < 0 \), the same technique yields

\[ Sf < \varphi_{\Delta}(Nf). \]

We now determine nth optimal information for \( F \). Let
\[\Delta_n^* \text{ and } \Delta_n\] denote the grids

\[\Delta_n^* := \{0 < t_1^* < \ldots < t_n^* < 1\} \text{ with } t_i^* := \left(\frac{2i}{2n+1}\right)^{1/r} \quad (1 \leq i \leq n)\]

and

\[\Delta_n := \{0 < x_1^* < \ldots < x_n^* < 1\} \text{ with } x_i^* := \frac{2i}{2n+1} \quad (1 \leq i \leq n),\]

respectively.

**Theorem 3.3:**

\[e(n,F) = e(n,G) = \frac{1}{4n+2} .\]

Moreover,

\[e(N^*,G) = e(n,G) \quad \text{iff} \quad \Delta = \Delta_n^*,\]

and

\[e(N^*,F) = e(n,F) \quad \text{iff} \quad \Delta = \Delta_n.\]

**Proof:** Immediate from Lemma 3.1, Theorem 3.1 and minimizing the right-hand side of (3.18) subject to the constraint

\[\sum_{i=0}^{n} t_i = 1.\]

Hence, sampling at the points \([t_1^*, \ldots, t_n^*]\) is nth optimal information for the class \(F\) of integrands. Note that the nth minimal error is finite for all \(n \geq 0\), and is \(O(n^{-1})\) as \(n \to \infty\). Thus we have found a situation in which the nth minimal
error algorithms all have finite error and are convergent, but do not integrate constants exactly.

**Remark 3.2:** We have shown that $\varphi_\Delta$ does not integrate constants exactly when $r \in \left( \frac{1}{2}, 1 \right)$. One can show that the nth minimal error algorithm $\varphi_{\Delta_n}^*$ does not integrate constants exactly when $r \in [\frac{1}{3}, \frac{1}{2} \cup [\frac{1}{2}, 1]$. We do not know whether this assumption on $r$ is needed. In fact, numerical testing indicates that the assumption may not be necessary.

We now discuss some open questions.

**Problem 3.1:** Although we know that the nth minimal-error algorithm does not integrate constants exactly, we do not know what the penalty is for using a quadrature rule that integrates constants exactly. For instance, if $\{\varphi_n\}_{n=1}^\infty$ is a sequence of quadrature rules which integrate constants exactly, and there exists $M > 0$ such that $e(\varphi_n, F) \leq Mn^{-1}$ for all sufficiently large $n$, then the complexity penalty for using $\{\varphi_n\}_{n=1}^\infty$, instead of $\{\varphi_{\Delta_n}^*\}_{n=1}^\infty$, in computing an $\varepsilon$-approximation is bounded as $\varepsilon \to 0$.

In such a case, it may be worthwhile to use the (perhaps simpler) rule $\varphi_n$, rather than $\varphi_{\Delta_n}^*$. Does such a sequence $\{\varphi_n\}_{n=1}^\infty$ exist?

**Problem 3.2:** Although $\varphi_{\Delta_n}^*$ does not integrate constants exactly, $\varphi_\Delta$ integrates the functions $f(t) = t^{r-1}$ and $f(t) = t^{2r-1}$
exactly when $t_n = 1$. Is there a function $f$ which is integrated exactly by $\gamma_n$ for all $n$? If so, does there exist a different class $F$ of integrands for which the linear optimal error algorithm $\varphi_n$ using $n$th optimal information is convergent, yet for which the only element of $F$ which is exactly integrated by $\varphi_n$ for all (sufficiently large $n$) is the zero function?
4. **Roughly-equidistant nodes can be terrible.**

In this Section, we show that the penalty for sampling at almost equidistant points (rather than optimal points) is unbounded, whether the penalty is measured by error or complexity.

We define $F$ as in Section 3, but now with $0 < r < \frac{1}{2}$. Recall that Theorem 3.3 states that the $n$th minimal error is $\Theta(n^{-1})$ as $n \to \infty$, and that sampling at the points $[t_1^*, \ldots, t_n^*]$ with $t_i^* = \left(\frac{2i}{2n+1}\right)^{1/r}$ ($1 \leq i \leq n$) is optimal.

We now ask how close sampling at "roughly-equidistant" nodes is to optimal. In order to make this precise, we will use information based on a sequence of grids $\{\Delta_n\}_{n=1}^{\infty}$ which is **quasi-uniform** (see e.g. [7].) That is, 

\[
\limsup_{n \to \infty} u(\Delta_n) < +\infty
\]

where

\[
\Delta_n := \{0 < t_{1,n} < \ldots < t_{n,n} \leq 1\}
\]

\[
t_{0,n} := 0 \quad t_{n+1,n} := 1
\]

\[
h_{i,n} := t_{i+1,n} - t_{i,n}
\]

\[
h(\Delta_n) := \max_{0 \leq i \leq n} h_{i,n}
\]

\[
u(\Delta_n) := \begin{cases} 
\max_{0 \leq i \leq n} \frac{h(\Delta_n)}{h_{i,n}} & \text{if } t_{n,n} \neq 1 \\
\max_{0 \leq i \leq n-1} \frac{h(\Delta_n)}{h_{i,n}} & \text{if } t_{n,n} = 1
\end{cases}
\]
(For example, a sequence of equidistant grids is quasi-uniform.)

Remark 4.1: The sequence \( \{\delta^*_n\}_{n=1}^\infty \) of optimal grids is not quasi-uniform. However, \( \delta^*_n \) is the image of \( \tilde{\delta}^*_n \) under the transformation \( \tau \), and \( \{\tilde{\delta}^*_n\}_{n=1}^\infty \) is quasi-uniform. That is, even though the optimal grid sequence is not quasi-uniform, there is a change of variables \( x = \tau^r \) such that the transformed grid sequence is quasi-uniform. Of course, this is precisely what is done in practice to remove the singularity at the origin.

We then have

Theorem 4.1: \( e(N,F) = \mathcal{O}(n^{-2r}) \).

Proof: Let

\[
\tilde{\delta}_n := \{0 < x_{1,n} < \ldots < x_{n,n} \leq 1\}
\]

with

\[
x_{i,n} := \tau(t_{i,r}) = \tau_{i,n}^r \quad (0 \leq i \leq n+1),
\]

and let

\[
\delta_{i,n} := x_{i+1,n} - x_{i,n} \quad (0 \leq i \leq n).
\]

Then Theorem 3.2 yields...
In what follows, we assume that $\delta_{n,n} > 0$; the grids for which $\delta_{n,n} = 0$ are handled analogously.

We next estimate $\delta_{0,n}, \ldots, \delta_{n,n}$. By quasi-uniformity of $\{\Delta_n\}_{n=1}^{\infty}$, we find that there exists $\alpha \geq 1$ such that

$$
\frac{1}{\alpha} \frac{1}{n+1} \leq h_{i,n} \leq \frac{\alpha}{n+1}
$$

and so

$$
\frac{i}{\alpha(n+1)} \leq t_{i,n} \leq \frac{i\alpha}{n+1}.
$$

We first consider $\delta_{0,n} = h_{0,n}$. Then

$$
\frac{1}{\alpha^r(n+1)^r} \leq \delta_{0,n} \leq \frac{\alpha^r}{(n+1)^r}.
$$

Now let $i \in \{1, \ldots, n\}$. By the mean-value theorem

$$
\delta_{i,n} = \frac{i}{(n+1)^r} (\tau_{i,n}) h_{i,n},
$$

where

$$
\frac{i}{(n+1)^r} h_{i,n} \leq \delta_{i,n} \leq \frac{i}{(n+1)^r} h_{i,n}.
$$

Since $\psi'' < 0$ on $(0,1)$, (4.11) and (4.12) yield

$$
\psi'\left(\frac{\alpha(n+1)^{r-1}}{n+1}\right) h_{i,n} \leq \delta_{i,n} \leq \psi'\left(\frac{\alpha}{(n+1)^r}\right) h_{i,n}.
$$

Hence (3.1), (4.8) and (4.13) yield
\[(4.14) \quad \frac{r}{\alpha^{2-r}} \left(\frac{1}{n+1}\right)^{r-1} \leq \beta_{i,n} \leq r^{2-r} \left(\frac{1}{n+1}\right)^{r-1}, \quad (1 \leq i \leq n).\]

Let
\[\sigma_{n,r} = \sum_{i=1}^{n} \binom{n}{i} \frac{1}{i^{2-2r}}.\]

\[(4.15) \quad C_1(\alpha, r) := \frac{r^{2}}{\alpha^{4-2r}}, \quad C_2(\alpha, r) := \max\{r^{2}, 4-2r, r^{2}\}.\]

Then \((4.8), (4.14)\) and \((4.15)\) yield
\[(4.16) \quad \frac{C_1(\alpha, r)}{(n+1)^{r}} \left(1 + \sigma_{n,r}\right) \leq \sum_{i=1}^{n} \beta_{i,n}^{2} \leq \frac{C_2(\alpha, r)}{(n+1)^{r}} \left(1 + \sigma_{n,r}\right).\]

Since \(r < \frac{1}{2}\), \(\sigma_{n,r}\) is a convergent series of positive terms, i.e., there exists \(\sigma_{r} > 0\) for which \(\sigma_{n,r} \leq \sigma_{r}\) for all \(n\).

Hence \((4.16)\) becomes
\[(4.17) \quad \frac{C_1(\alpha, r)}{(n+1)^{r}} \leq \sum_{i=0}^{n} \beta_{i,n}^{2} \leq \frac{C_2(\alpha, r)}{(n+1)^{r}} \left(1 + \sigma_{r}\right).\]

The result now follows from \((4.7)\) and \((4.17)\). \(\square\)

As an immediate consequence, we see the penalty, in terms of optimal error, for using quasi-uniform nodes:

\[\text{Corollary 4.1:} \quad \frac{e(N, n, F)}{e(n, F)} = 3(n-2r) \to +\infty \quad \text{as } n \to \infty. \]
We next investigate the penalty, in terms of complexity, for using quasi-uniform information. Let \( \text{comp}^*(\varepsilon; F) \) denote the \( \varepsilon \)-complexity when using information based on a quasi-uniform grid sequence, i.e.,

\[
\text{comp}^*(\varepsilon; F) := \inf\{\text{comp}(\omega): \varepsilon(\omega, F) \leq \varepsilon \quad \text{and} \quad \omega \in \bigcup_{n=1}^{\infty} \{N_{\Delta_n}^F\} \}.
\]

Then results from [10] yield that

\[
\text{comp}^*(\varepsilon; F) = \Omega(m^*(\varepsilon; F)) \quad \text{as} \quad \varepsilon \to 0,
\]

where

\[
m^*(\varepsilon, F) := \inf\{n: \varepsilon(N_{\Delta_n}^F) \leq \varepsilon\}
\]

may be thought of as an \( \varepsilon \)-cardinality number for information based on a quasi-uniform grid sequence.

We then have

**Corollary 4.2:**

\[
\frac{\text{comp}^*(\varepsilon; F)}{\text{comp}(\varepsilon, F)} = \Omega\left(\frac{1}{\varepsilon^{1/2}}\right) \to \infty \quad \text{as} \quad \varepsilon \to 0.
\]

**Proof:** From (4.20) and Theorem 4.1, we have

\[
m^*(\varepsilon, F) = \Omega\left(\frac{1}{\varepsilon^{1/2}}\right) \quad \text{as} \quad \varepsilon \to 0.
\]
Hence (4.19) and (4.21) yield

\[ \text{comp}^* (\varepsilon, F) = \Theta \left( \frac{1}{\varepsilon} \right)^{1/2} \] as \( \varepsilon \to \infty. \]

On the other hand, Theorem 3.3 implies that

\[ m (\varepsilon, F) = \Theta \left( \frac{1}{\varepsilon} \right) \] as \( \varepsilon \to \infty. \]

Hence (2.13) and (4.23) imply

\[ \text{comp} (\varepsilon, F) = \Theta \left( \frac{1}{\varepsilon} \right) \] as \( \varepsilon \to \infty. \]

The Corollary follows from (4.22) and (4.24). □

Hence, Corollaries 4.1 and 4.2 tell us that the penalty for using information based on a quasi-uniform sequence of grids, whether measured by error or complexity, is unbounded. However, the optimal grid sequence becomes quasi-uniform after a change of variables. This leads to an open question:

**Problem 4.1:** Does there exist a bounded convex class \( F \) of integrands such that the \( n \)th minimal error is finite for all \( n \) and converges to zero as \( n \to \infty \), and for which there is no change of variables under which the sequence of optimal grids becomes quasi-uniform? □
5. Quadrature is Arbitrarily Hard

In this Section we show that \( F \) may be chosen so that the \( n \)th minimal error goes to zero as slowly as we like. Hence, the \( \varepsilon \)-complexity can be a function which goes to infinity (for \( \varepsilon \to 0 \)) as quickly as we desire. See [1] for a related result.

To this end, we let \( \psi: [0,2] \to \mathbb{R} \) satisfy

\[
\psi \in C[0,2] \cap C^1(0,2),
\]

\[
\psi' > 0 \quad \text{on} \quad (0,2),
\]

(5.1)

\[
\psi(0) = 0, \quad \text{and}
\]

\[
\limsup_{t \to \infty} \frac{\psi(t)}{t} > 0 \quad \text{(possibly infinite)}.
\]

Define a seminorm \( \| \cdot \|_\psi \) and a norm \( \| \cdot \|_\psi \) on \( C^1[0,1] \) by

\[
(5.2) \quad \| f \|_\psi := \text{ess sup} \frac{|f(t')-f(t)|}{\psi(2t-2t')} \quad 0 \leq t < t' < 1
\]

and

\[
(5.3) \quad \| f \|_\psi := \max \{ \| f \|_{L^\infty(0,1)}, \| f \|_\psi \}.
\]

Let \( \mathcal{W}_\psi \) be the Banach space given by the \( \| \cdot \|_\psi \)-closure of \( C^1[0,1] \) in \( L^\infty(0,1) \). Finally, let

\[
(5.4) \quad F := \{ f \in \mathcal{W}_\psi : \| f \|_\psi \leq 1 \}. 
\]
Remark 5.1: Our motivating example is given by \( \gamma(t) := t^2 \) (\( 0 < \alpha < 1 \)), in which case \( W_\gamma = \text{Lip } \alpha \), (see e.g. [5]).

Another \( \gamma \) satisfying (5.1) is \( \gamma(t) := (\ln \frac{1}{t})^{-\alpha} \), where \( \alpha > 0 \). Note that (5.1) tells us that \( \gamma \) is a modulus of continuity, see [6].

Our results will be first stated in terms of the function \( \rho : [0,1] \to \mathbb{R} \) given by

\[
\rho(h) := \begin{cases} 
\frac{1}{h} \int_0^h \gamma(t) \, dt & \text{if } h > 0 \\
0 & \text{if } h = 0 
\end{cases}
\]  

(5.5)

By L'Hospital's rule, \( \rho \) is continuous. We will first show that \( e(n,F) = \rho(\frac{1}{n}) \). We will then show a mild smoothness condition on \( \gamma \) which will imply that \( \rho(h) = \mathcal{O}(\gamma(h)) \) as \( h \to 0 \).

This will yield the result \( e(n,F) = \mathcal{O}(\gamma(\frac{1}{n})) \) as \( n \to \infty \).

Remark 5.2: We briefly comment on (5.1). Recall that \( \gamma(\frac{1}{n}) \) will (essentially) be the nth minimal error. The first three conditions are equivalent to the requirement that the nth minimal error decrease as \( n \) increases, going to zero as \( n \to \infty \). The final condition tells us that the nth minimal error is \( n^{-1} \) as \( n \to \infty \) (i.e. the problems are not too easy); moreover, if it does not hold, then \( W_\gamma \) consists only of constant functions.
We first determine the optimal error, the nth minimal error, the nth optimal information, and the nth minimal error algorithm in

**Theorem 5.1:**

(i) The optimal error among algorithms using $N_\Delta$ is

$$e(N_\Delta, F) = \frac{1}{2} \int_0^1 \psi + \sum_{i=1}^{n-1} \int_0^{h_i} \psi + \frac{1}{2} \int_0^{h_n} \psi,$$

where

$$h_i := t_{i+1} - t_i \quad (0 \leq i \leq n)$$

with

$$t_0 := 0 \quad \text{and} \quad t_{n+1} := 1.$$

(ii) The nth minimal error is

$$e(n, F) = \frac{1}{n}$$

and

$$N^* f := \left[ f(t^*_1) \ldots f(t^*_n) \right],$$

with

$$t^*_i = \frac{2i-1}{2n} \quad (1 \leq i \leq n)$$

is the unique n-th optimal information.

(iii) The composite midpoint rule

$$\varphi_n(N^* f) := \frac{1}{n} \sum_{i=1}^{n} f(t^*_i)$$
(with $t_1$ as in (5.9)) is an $n$th minimal error algorithm, with

\[(5.11) \quad e(\varphi_n, F) = 2 \left( \frac{1}{n} \right) .\]

**Proof (i):** Let

\[
(5.12) \quad z_\Delta(t) := \begin{cases} 
\psi(2t_1-2t) & 0 \leq t \leq t_1 \\
\psi(2t-2t_1) & t_1 \leq t \leq t_1 + \frac{1}{2} h_1 \\
\psi(2t_i-2t) & t_i - \frac{1}{2} h_{i-1} \leq t \leq t_i \\
\psi(2t-2t_i) & t_i \leq t \leq t_i + \frac{1}{2} h_i \\
\psi(2t_n-2t) & t_n - \frac{1}{2} h_{n-1} \leq t \leq t_n \\
\psi(2t-2t_n) & t_n \leq t \leq 1 
\end{cases} \quad (2 \leq i \leq n-1)
\]

Then $z_\Delta \in F \cap \ker N_\Delta$ and

\[(5.13) \quad -z_\Delta(t) \leq z(t) \leq z_\Delta(t) \quad (0 \leq t \leq 1) \ \forall z \in F \cap \ker N_\Delta .\]

As in the proof of Theorem 3.1 (5.13) yields.

\[(5.14) \quad e(N_\Delta, F) = \int_0^1 z_\Delta(t) dt .\]

So (5.6) follows from (5.12) and (5.14) by a straightforward calculation.

(ii) follows by minimizing the right-hand side of (5.6) subject to the constraint $\sum_{i=0}^{n} h_i = 1$.

(iii) Let $f \in F$ and set $h = \frac{1}{2n}$. Then
and, analogously,

\[
\int_{t_1}^{t_1+h} |f(t) - f(t_1^*)| \, dt \leq \frac{1}{2} \int_{0}^{1/n} \gamma(t) \, dt. \tag{5.16}
\]

So (5.5), (5.15) and (5.16) yield

\[
|\int_{0}^{1} f(t) \, dt - \varphi_n(N^*F)| \leq 2n \cdot \frac{1}{2} \int_{0}^{1/n} \gamma(t) \, dt \nonumber
\]

\[
= n \int_{0}^{1/n} \gamma(t) \, dt
\]

\[
= \varphi \left( \frac{1}{n} \right). \tag{5.17}
\]

Since \( f \in F \) is arbitrary, we find \( e(\varphi_n, F) \leq \varphi \left( \frac{1}{n} \right) \). On the other hand, \( \varphi_n \in \varphi(N^*F) \), so that \( e(\varphi_n, F) \geq e(N^*F) = \varphi \left( \frac{1}{n} \right) \).

Hence, \( e(\varphi_n, F) = \varphi \left( \frac{1}{n} \right) \). Completing the proof. \( \square \)

We now turn to complexity. Using (2.13) and (2.14), the results of Theorem 5.1 immediately yield

**Theorem 5.2:**

(i) The \( \varepsilon \)-complexity satisfies

\[
(c+1)m(\varepsilon, F) - 1 \leq \text{comp}(\varepsilon, F) \leq (c+1)m(\varepsilon, F) \tag{5.18}
\]

where
(5.19) \[ m(\varepsilon, F) = \frac{1}{\rho^{-1}(\varepsilon)} \]

(ii) \( \varphi_n \), with \( n = m(\varepsilon, F) \), is an algorithm for which

(5.20) \[ e(\varphi_n, F) \leq \varepsilon \quad \text{and} \quad \text{comp}(\varphi_n) \leq (c+1) \, m(\varepsilon, F). \]

Hence \( \varphi_n \) with \( n = m(\varepsilon, F) \) is (disregarding one arithmetic operation) an optimal complexity algorithm for \( \varepsilon \)-approximation, and

(5.21) \[ \text{comp}(\varepsilon, F) \sim \frac{c+1}{\rho^{-1}(\varepsilon)} \quad \text{as} \quad \varepsilon \to 0. \]

Finally, we wish to translate the dependence in Theorems 5.1 and 5.2 on \( \rho \) into dependence on the original function \( \psi \). To do this, we impose a mild smoothness condition on \( \psi \), namely, that

(5.22) \[ \exists : = \lim_{n \to 0} \frac{h \psi'(h)}{\psi(h)} \]

exists and is finite. (Note that this holds for the functions mentioned in Remark 5.1.) Then L'Hospital's rule gives

(5.23) \[ \lim_{h \to \infty} \frac{\phi(h)}{\psi(h)} = \frac{1}{1+\beta} \]

Using (5.23) and Theorems 5.1 and 5.2, we have

**Theorem 5.3:**

(i) \[ e(n, F) \sim \frac{1}{1+\beta} \, \frac{1}{\psi(\frac{1}{n})} \quad \text{as} \quad n \to \infty. \]
(ii) $\text{comp}(\varepsilon, F) \sim \frac{c + 1}{\psi^{-1}((1+\beta)\varepsilon)}$ as $\varepsilon \to 0$. 

Since $\psi$ is essentially an arbitrary function, this tells us that quadrature can be arbitrarily hard.
