Received 4 May 2012; revised 30 August 2012; accepted 30 August 2012; published 4 October 2012.

[1] Existing paleoclimate data suggest a complex evolution of hydroclimate within the Indo-Pacific Warm Pool (IPWP) during the Holocene epoch. Here we introduce a new leaf wax isotope record from Sulawesi, Indonesia and compare proxy water isotope data with ocean-atmosphere general circulation model (OAGCM) simulations to identify mechanisms influencing Holocene IPWP hydroclimate. Modeling simulations suggest that orbital forcing causes heterogeneous changes in precipitation across the IPWP on a seasonal basis that may account for the differences in time-evolution of the proxy data at respective sites. Both the proxies and simulations suggest that precipitation variability during the September–November (SON) season is important for hydroclimate in Borneo. The preëminence of the SON season suggests that a seasonally lagged relationship between the Indian monsoon and Indian Ocean Walker circulation influences IPWP hydroclimatic variability during the Holocene.

1. Introduction

[2] Variability in the hydrological cycle within the Indo-Pacific Warm Pool (IPWP) is an important component of the global climate system: perturbations in deep tropical convection reverberate through oceanic and atmospheric teleconnections and affect both tropical and extratropical climates [e.g., Ropelewski and Halpert, 1987]. Many uncertainties remain regarding the dynamics of IPWP hydroclimate, including the response of Indo-Pacific Walker circulation to both past and future global temperature change [Vecchi et al., 2006; Karneus et al., 2009; DiNezio et al., 2010, 2011]. Paleoclimate investigations that use both proxy data and modeling simulations provide an opportunity to improve our understanding of the hydrological cycle in the IPWP: by studying the response of IPWP hydroclimate to large, known climate forcings in the past – such as changes in the Earth's

orbit – it is possible to both assess our ability to correctly simulate tropical climates and identify mechanisms that govern IPWP climate response to external forcing.

[3] Paleoclimate archives that record water isotopes are useful tracers for IPWP hydroclimate, as water isotopes in the deep tropics track the amount of regional rainfall as well as synoptic-scale convective behavior [LeGrande and Schmidt, 2009; Lewis et al., 2010; Pausata et al., 2011; Tierney et al., 2011]. To date, there are two speleothem-based records of the oxygen isotopic composition of precipitation within the IPWP: one from Borneo, Malaysia [Partin et al., 2007] and another from Flores, Indonesia [Griffiths et al., 2009]. The two records depict markedly different trends in hydroclimate since the last deglaciation, suggesting regional heterogeneity within the IPWP that begs explanation. Partin et al. [2007] and Griffiths et al. [2009, 2010a] speculated that a mixture of forcing mechanisms – the influence of Earth's precession on deep convection in the IPWP, the position of the Inter-Tropical Convergence Zone (ITCZ) and rising sea levels (for the earliest Holocene) – might explain the observed patterns. Any of these mechanisms is plausible, but none have been tested against general circulation model experiments.

[4] Here we add a third IPWP isotopic record from offshore Sulawesi, Indonesia, a site that sits precisely between Borneo and Flores (Figure 1). We use a different isotopic archive – the hydrogen isotopic composition of leaf waxes (δD_{wax}) deposited in a marine sediment core – to reconstruct central IPWP hydroclimate for the last 15,000 years. Using isotopic information from three locations in the IPWP, we compare the proxy data to simulations conducted with coupled ocean-atmosphere general circulation models

Figure 1. Locations of the three proxy sites discussed in the main text: speleothem $\delta^{18}\text{O}$ from northwestern Borneo [Partin *et al.*, 2007], sedimentary $\delta\text{D}_{\text{wax}}$ from offshore Sulawesi (this study) and speleothem calcite and inclusion $\delta^{18}\text{O}$ from the island of Flores [Griffiths *et al.*, 2009, 2010b].

(OAGCMs), including the mid-Holocene (6K) simulations conducted as part of the Paleoclimate Intercomparison Project Phase II (PMIP2) and Holocene timeslice simulations conducted with the fully coupled, isotope-enabled Goddard Institute for Space Studies (GISS) ModelE-R. Using the proxy and model data in tandem, we discuss the mechanisms influencing IPWP hydroclimate and water isotopes during the Holocene epoch.

2. Methods

2.1. Proxy Data

[5] We measured the hydrogen isotopic composition of leaf waxes ($\delta\text{D}_{\text{wax}}$) in marine sediment core BJ8-03-70GGC

(3.566°S, 119.383°E, 482 meters water depth), located 12 km off the southwest shore of Sulawesi in the Makassar Strait (Figure 1). Thirteen radiocarbon dates constrain the depth-age model for core 70GGC (Table 1) which is also described in Linsley *et al.* [2010] and Gibbons [2012]. The age model is based on a linear interpolation of the depth-age relationship between calibrated dates with the additional assumption that the top of the core is equivalent to 0 yr BP. Core 70GGC was sampled every ~ 100 years downcore, with somewhat higher resolution during the middle Holocene (near 4 ka) and the Younger Dryas chronozone (12.7–11.5 ka). $\delta\text{D}_{\text{wax}}$ analyses were conducted as previously described in Tierney *et al.* [2010]. Briefly, freeze-dried sediments were extracted with a solvent mixture of dichloromethane:methanol (9:1,v/v) using an Accelerated Solvent Extractor. Leaf waxes were purified from the resulting total lipid extract via NH_2 column chromatography, methylated with methanol of a known isotopic composition, and then further purified via silica gel chromatography. The C_{30} fatty acid was analyzed in triplicate for its hydrogen isotopic composition via gas chromatography-isotope ratio monitoring-mass spectrometry (GC-IR-MS), using a Thermo Delta XL mass spectrometer at Brown University. H_2 standard gas calibrated to VSMOW was injected three times before and after the sample lipid peaks as an internal standard. In addition, an external fatty acid methyl ester (FAME) standard of known isotopic composition was run every nine injections to monitor drift. Isotopic values were corrected for the added methyl group. Results presented here are triplicate means, and average triplicate standard error was 0.7‰.

[6] $\delta\text{D}_{\text{wax}}$ is an emerging proxy for the isotopic composition of precipitation and has been widely applied in tropical settings [e.g., Schefuß *et al.*, 2005; Tierney *et al.*, 2008], including at a nearby core site from the Makassar Strait [Tierney *et al.*, 2010]. However, changes in wax source, including changes in vegetation or biomes through time, can complicate its fidelity as a recorder of the isotopes of precipitation [Sachse *et al.*, 2012, and references therein]. With regards to the geographic source of the leaf waxes, given the humid (precipitation rates of 2–3 m/yr) tropical forest environment of southern Sulawesi, the proximity of the core site to the shore (12 km, Figure 1), and the high accumulation rates along the Sulawesi margin attributable to terrestrial

^aFrom Linsley *et al.* [2010] and Gibbons [2012]. The ^{14}C ages were calibrated with the Marine09 curve using Calib 6.0 [Reimer *et al.*, 2009] with $\Delta R = 0$. Depth-age pairs were linearly interpolated to every cm between dated intervals to form an age model, with the additional assumption that the coretop corresponds to 0 yr BP.

Figure 2. Observed and simulated seasonal cycles of precipitation for the Borneo, Sulawesi, and Flores sites (Figure 1). Blue lines represent the observed mean seasonal cycle of precipitation from the Global Precipitation Climatology Centre (GPCC) v5 gridded precipitation product (<http://gpcc.dwd.de>) [Rudolf *et al.*, 2011], shading indicates the 68% confidence intervals. Black lines represent GISS ModelE-R simulated precipitation from the control experiment (0K). Red lines represents the simulated multimodel mean of 11 PMIP2 OAGCMs. For the simulated data, values are the mean of gridcells spanning 2–6°N, 112.5–117.5°E (for northern Borneo), 2–6°S, 117.5–122.5°E (for Sulawesi) and 10°S, 117.5–122.5°E (for Flores).

input (40–100 cm/ka [Oppo *et al.*, 2009; Linsley *et al.*, 2010]) we assume that the waxes at Site 70GGC have always been locally derived from southern Sulawesi and predominantly transported by fluvial processes. Vegetation changes through time are a greater concern as pollen evidence from northern Sulawesi indicates expansion of grasslands during the deglacial period [Dam *et al.*, 2001]. Based on the apparent fractionation of studied grasses [Sachse *et al.*, 2012], the effect of having grasses contribute proportionally more to the δD_{wax} signal during the deglaciation would be to attenuate the magnitude of the primary water isotope signal. From this perspective, the deglacial changes in δD_{wax} can be considered a minimum estimate. At around 10 ka, a forested woodland similar to today's became established on Sulawesi [Dam *et al.*, 2001] and lower-resolution analyses of the carbon isotopic composition of leaf waxes in 70GGC indicate variability of less than 3‰ (J. Saenz *et al.*, manuscript in preparation, 2012) indicating a relatively stable Holocene landscape. These data suggest that δD_{wax} can be confidently interpreted as a primary recorder of the δD of precipitation across the timeframe of interest here. Nevertheless, our interpretation of the climatic meaning of the δD_{wax} data is deliberately carried out through tandem use of the existing speleothem and foraminiferal $\delta^{18}O$ data and isotope-enabled modeling experiments.

2.2. Model Simulations

[7] We obtained simulated precipitation fields from the pre-industrial control (0K) and mid-Holocene (6K) experiments conducted as part of the Paleoclimate Intercomparison Project 2 (PMIP2) [Braconnot *et al.*, 2007] from all available fully coupled OAGCM models archived in the PMIP2 database, which includes CSIRO-MkL1.1, IPSL-CM4, CCSM3.0, FGOALS-g1.0, MIROC3.2, FOAM, MRI-CGCM2.3.4fa, MRI-CGCM2.3.4nfa, GISS ModelE-R, ECHAM5-MPI, and HadCM3M2. The mid-Holocene experiments were forced with orbitally induced changes in solar insolation as well as

greenhouse gases estimated from ice core data. Details of the models and the parameters used for the PMIP2 modeling experiments are available online at <http://pmip2.lsce.ipsl.fr>. We also use precipitation and hydrogen and oxygen isotopes of precipitation fields from time slice simulations conducted with one of the PMIP2 models, the isotope-enabled GISS ModelE-R. Time slice simulations were conducted for 9K, and then every 1K from 6–0K. Similar to the PMIP2 protocol, these experiments were forced with insolation changes and greenhouse gases. The 9K GISS time slice simulation incorporates a remnant Laurentide ice sheet, with mean ocean salinity and $\delta^{18}O$ adjusted to account for the associated ice volume changes (35 psu, +0.33‰, equivalent to 35 meters of sea level change). Further details of the model, parameters used for the time slice simulations, as well as global results are described in LeGrande and Schmidt [2009].

[8] Though the sites of interest to this study (Borneo, Sulawesi, and Flores) are geographically close to one another (Figure 1), they experience different seasonal cycles in precipitation. GISS ModelE-R and the multimodel mean, respectively, reasonably approximate the distinct seasonal cycle of precipitation at these locales (Figure 2). This suggests that in spite of the relatively low spatial resolution of the PMIP2 OAGCMs, we can use the results of these simulations to investigate hydroclimate in this region with some confidence.

3. Results and Discussion

[9] The δD_{wax} data from core 70GGC are relatively enriched (−155‰) near 15,000 yr BP, then trend toward more depleted values (−170‰) until ca. 8,000 yr BP, after which they stabilize (Figure 3a). Higher-frequency variability punctuates the δD_{wax} record throughout, including an enrichment event at ~900 yr BP during the Medieval Climate Anomaly (MCA) that replicates the result of Tierney *et al.* [2010]. The data also show abrupt depletion around 11 ka, sustained depletion near 4 ka, and an enrichment event at 3 ka

Figure 3. (a) Leaf wax hydrogen isotope data (δD_{wax}) from marine sediment core 70GGC. Gray error bars represent the analytical 95% confidence intervals. Red line represents a 500-yr gaussian smoothing of the data to emphasize long-term trends. Red triangles indicate the stratigraphic locations of ^{14}C dates (Table 1). MCA marks the Medieval Climate Anomaly and an enrichment event that replicates the result of Tierney *et al.* [2010]. Dotted lines mark the beginning and end of the Younger Dryas chronozone (YD), when no change in Sulawesi δD_{wax} is observed. Other notable enrichment and depletion events as described in the main text are indicated. (b) Makassar Strait $\delta^{18}O_{sw}$, reconstructed from paired foraminiferal Mg/Ca and $\delta^{18}O$ measurements in several marine sediment cores including 70GGC [Linsley *et al.*, 2010]. Gray error bars represent the compounded analytical and core-compositing uncertainty.

(Figure 3a). There is no anomaly in δD_{wax} associated with the Younger Dryas (YD) event, similar to the speleothem $\delta^{18}O$ data from Borneo [Partin *et al.*, 2007], but unlike the speleothem $\delta^{18}O$ record from Flores, which show isotopic depletion during the YD [Griffiths *et al.*, 2009].

[10] Comparison between δD_{wax} and a reconstruction of seawater $\delta^{18}O$ ($\delta^{18}O_{sw}$) from the Makassar Strait (Figure 3b) indicates that both isotopic proxy records evolve similarly, with a linear trend toward isotopic depletion from 15–8 ka followed by relative stability during the rest of the Holocene. The 15–8 ka trend integrates several influences on IPWP water isotopic composition, including changes in global ice volume, regional temperature, oceanic and atmospheric advection of fresh water into and out of the IPWP, and local rainfall amount. SST proxy data suggest that regional temperatures rose ca. $1.5^{\circ}C$ across this time interval [Linsley *et al.*, 2010], which would only induce a minor (ca. 1.5‰ for δD , 0.19‰ for $\delta^{18}O$) [Majoube, 1971] change in the isotopic composition of rainfall, and ice volume can only account for an additional ca. 4‰ and 0.5‰ for δD and $\delta^{18}O$, respectively (scaling inferred sea level changes to a glacial ocean enrichment of 1‰) [Schrag *et al.*, 1996]. Thus, the remaining ca. 9‰ (0.7‰) change between 14 and 8 ka in the Sulawesi δD_{wax} ($\delta^{18}O_{sw}$) record represents regional hydrological change. Seawater enrichment in the IPWP during the deglaciation and early Holocene is a robust feature of $\delta^{18}O_{sw}$ proxy records from the region [Stott *et al.*, 2004; Oppo *et al.*, 2007; Linsley *et al.*, 2010] and has been explained by increased export of water vapor to the Asian continent and Indian Ocean as a result of an intensified monsoon, an increase in the advection of salty waters from the central Pacific, and reduced transport of water vapor across the Panama isthmus [Oppo *et al.*, 2007; LeGrande and Schmidt, 2011]. The isotopic enrichment may also reflect a reduction in regional rainfall amount. Previous GISS ModelE-R isotope-enabled simulations [Lewis *et al.*, 2010] identified rainfall amount as the climate parameter best correlated with precipitation isotopic variability in the Indonesian archipelago, and the timeslice simulations from GISS ModelE-R used here indicate that mean annual changes in precipitation amount and precipitation isotopes over Sulawesi during the Holocene (excluding 9K due to the simulated impact of ice volume) are strongly correlated ($r = 0.94$). Thus, the 15–8 ka trend in the Sulawesi δD_{wax} data in particular likely reflects a shift from a drier deglacial period to wetter conditions during the Holocene. The simplest explanation for a dry deglacial period is a thermodynamic one (cooler temperatures cause reduced humidity and precipitation in the wet tropics) [e.g., Clement *et al.*, 2004], but exposure of the Sunda Shelf may have promoted more severe regional divergence and drying [DiNezio *et al.*, 2011].

[11] The absence of a trend from 8–0 ka in Sulawesi δD_{wax} suggests that changes in the seasonal distribution of insolation (i.e., orbital precession) had little apparent effect on the isotopes of precipitation at this location and that meridional movement of the ITCZ – oft-invoked to explain rainfall isotopic evolution elsewhere in the tropics on this timescale [Burns, 2011] – is not relevant for this sector of the deep tropics. Likewise, speleothem $\delta^{18}O$ records from Borneo and Flores depict a complex time-evolution of IPWP water isotopes not immediately evocative of precessional influence (Figure 4). Like Sulawesi δD_{wax} , these records show a trend from 15–8 ka, which suggests that deglacial forcings (changing ice volume, exposure of the Sunda Shelf) affected water isotopes uniformly across the Indonesian region. Yet

Figure 4. Simulated and proxy-reconstructed isotopic data from the IPWP (Partin *et al.* [2007], Griffiths *et al.* [2009, 2010b] and this study). Calcite $\delta^{18}\text{O}$ and $\delta\text{D}_{\text{wax}}$ data are plotted as 100-year gaussian-smoothed series to emphasize lower frequency variability, with analytical 95% confidence intervals. Fluid inclusion data from Flores [Griffiths *et al.*, 2010b] are plotted with 1σ analytical error bars. Data are uncorrected for ice volume effects to facilitate comparison with the GISS ModelE-R timeslice results. Mean annual (solid lines) and SON (dotted lines) simulated precipitation isotopes from the GISS ModelE-R timeslice experiments are plotted on top of the proxy data; error bars indicate the 1σ variation in the decadal means. For simulated isotopic values we show the precipitation-weighted mean $\delta^{18}\text{O}$ or δD value from the same spatial boxes defined in Figure 2, normalized to the Holocene proxy mean for visual clarity. The anomalies in the proxy and model data are comparable. Dotted lines denote the Younger Dryas (YD) as in Figure 3.

after 8 ka, the records diverge. At Borneo, the monotonic trend in $\delta^{18}\text{O}$ continues until 4 ka with a change in $\delta^{18}\text{O}$ between 10–4 ka of $\sim 1.5\text{‰}$ (Figure 4). In contrast, the $\delta^{18}\text{O}$ record from Flores shows millennial-scale oscillations during the Holocene and more enriched $\delta^{18}\text{O}$ near 4 ka (Figure 4).

[12] In addition to calcite $\delta^{18}\text{O}$, Griffiths *et al.* [2010b] measured the $\delta^{18}\text{O}$ of fluid inclusions within the Flores speleothem, which is presumably representative of the isotopic composition of the source water from which the calcite precipitated (Figure 4). While fluid inclusion $\delta^{18}\text{O}$ shares the deglacial trend with the calcite $\delta^{18}\text{O}$, its evolution is different during the Holocene in that it indicates more depleted values at 4–5 ka. The difference between calcite $\delta^{18}\text{O}$ and inclusion $\delta^{18}\text{O}$ may reflect the effect of changing cave temperatures on the fractionation between drip water and calcite. During the mid-Holocene, this difference is 0.7‰ , which would theoretically imply that temperatures in the Flores cave were $\sim 3^\circ\text{C}$ colder than present [Griffiths *et al.*, 2010b]. This possible temperature effect is significant in the context of the 1‰ variability in Holocene calcite $\delta^{18}\text{O}$. (Figure 4). Although the errors on the fluid inclusion measurements are large (Figure 4) and thus allow for a wide range in possible cave temperature estimates, these data present a possibility that cave temperatures influenced Flores calcite $\delta^{18}\text{O}$ significantly, independent of rainfall $\delta^{18}\text{O}$. Given this possibility along with the lack of replication of the record in a different cave, our conservative interpretation of the $\delta^{18}\text{O}$ data from the Flores is that they do not resolve a mean change in local rainfall $\delta^{18}\text{O}$ across the Holocene. In this sense, the Flores data are in rough agreement with the $\delta\text{D}_{\text{wax}}$ data from Sulawesi. While cave temperatures could have influenced the Borneo record as well, unlike Flores the Borneo data were replicated in different caves 5 km apart [Partin *et al.*, 2007]. A temperature overprint would thus require coordinated temperature variability between caves, presumably dictated by large changes in air temperatures. As SST proxy data suggest that temperatures were relatively stable in the IPWP across the Holocene [Linsley *et al.*, 2010], this seems unlikely. In sum, the Holocene IPWP proxy isotopic data suggest peak depletion in $\delta^{18}\text{O}$ at Borneo from 4–5 ka, but no detectable change in the mean isotopic composition of rainfall at Sulawesi and Flores.

[13] If we accept that the differences between the proxy data sites are correct, the question then arises, why are the water isotope data different between these sites? We turn to simulations of IPWP hydroclimate in coupled OAGCMs to seek answers. First, we use the GISS ModelE-R timeslice simulations to directly compare simulated water isotopes with the proxy data (Figure 4). Weighted mean annual precipitation isotopes are enriched at 9K relative to 0K but then change little across the rest of the Holocene at all three sites, in general agreement with the proxy data at Sulawesi and Flores, but not at Borneo. Rather, calcite $\delta^{18}\text{O}$ at Borneo shows a better match with the simulated SON-season oxygen isotopic composition of precipitation ($\delta^{18}\text{O}_p$), both of which show maximum depletion at 4 ka (Figure 4). An observational study of the seasonal cycle of isotopes in precipitation in northern Borneo found that the time of maximum depletion in precipitation isotopes occurs during SON, when much of the water vapor originates from more remote southeasterly sources [Cobb *et al.*, 2007]. Thus, rainfall variability during SON can strongly influence weighted mean-annual $\delta^{18}\text{O}_p$. GISS

Figure 5. Comparison between an ad-hoc estimation of the seasonal cycle in precipitation $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_p$) in northern Borneo, based on a three-year time series of observed rainwater and dripwater $\delta^{18}\text{O}$ (black) [from Cobb *et al.*, 2007] and the simulated seasonal cycle in $\delta^{18}\text{O}_p$ in northern Borneo by GISS ModelE-R (blue).

ModelE-R simulates this seasonal cycle in $\delta^{18}\text{O}_p$ at Borneo remarkably well (Figure 5), and as is the case with the observational data [Cobb *et al.*, 2007], simulated $\delta^{18}\text{O}_p$ has

only a weak correlation ($r = 0.28$) with the seasonal cycle in rainfall amount (in contrast, simulated precipitation and $\delta^{18}\text{O}_p$ are strongly correlated at both the Sulawesi and Flores sites, $r = 0.84$ and $r = 0.92$, respectively). The mismatch between simulated mean annual $\delta^{18}\text{O}_p$ and proxy $\delta^{18}\text{O}$ at Borneo, then, does not reflect a fundamental deficiency in the model, but rather may simply indicate that the model is underestimating the amount of SON rainfall at 4K and/or the contribution of water vapor from the southeasterly source. Regardless, the depletion at 4 ka (Figure 4) seen only in the Borneo proxy record suggests a hydroclimatic response that is seasonal in nature and primarily affects the Borneo land-mass and immediate vicinity.

[14] What mechanisms might cause a unique hydroclimatic response in Borneo? Though we do not have multimodel simulations specifically at 4 ka, the multimodel mean of 6K precipitation simulated by 11 OAGCMs participating in PMIP2 (which includes GISS ModelE-R) yields insight into robust seasonal changes in mid-Holocene IPWP climate that may partially explain the heterogeneity in the proxy data. On a mean annual basis, the simulated changes in precipitation at 6K relative to 0K are close to zero (+0.1 mm/day, 6K–0K), in general agreement with the proxy isotopic data specifically at 6K (Figure 4). However, on a seasonal basis there is a heterogeneous response of hydroclimate to mid-Holocene climate conditions between Borneo, Sulawesi, and Flores (Figure 6). In boreal summer (June–July–August, JJA), precipitation increases at 6K relative to 0K over large landmasses in central Indonesia, causing wetter conditions over Borneo and Sumatra. In contrast, Sulawesi and Flores experience little change. Conversely, in boreal winter (December–January–February, DJF) precipitation decreases over all large land

Figure 6. Multimodel mean of seasonal changes precipitation for the mid-Holocene (6K) relative to the preindustrial control (0K), as simulated by 11 PMIP2 OAGCMs: CSIRO-MkL1.1, IPSL-CM4, CCSM3.0, FGOALS-g1.0, MIROC3.2, FOAM, MRI-CGCM2.3.4fa, MRI-CGCM2.3.4nfa, GISS ModelE-R, ECHAM5-MPI, and HadCM3M2. B, S, and F = locations of the Borneo, Sulawesi, and Flores proxy isotope data. Stippling indicates regions where all 11 models agree on the sign of change.

Figure 7. The 9K versus 4K anomalies in precipitation and the oxygen isotopes of precipitation simulated by GISS ModelE-R. Stippling indicates significant ($p < 0.05$) changes based on comparison with average decadal variability. B, S, and F = locations of the Borneo, Sulawesi, and Flores proxy isotope data.

surfaces in the IPWP – both north and south of the equator – and increases over the Indian ocean (Figure 6). Flores, as a small island, experiences slightly wetter conditions during this season as precipitation shifts from land to sea, whereas Borneo is slightly drier. Generally speaking, the seasonal redistribution of precipitation at 6K in the Indo-Pacific shows little meridional structure; rather, the changes in precipitation are from land to sea and vice versa. This reflects a differential influence of enhanced insolation seasonality, wherein increased insolation during the JJA season at 6K heats landmasses faster relative to the ocean, enhancing monsoonal circulation throughout the northern hemisphere and in the equatorial tropics, and decreased insolation during the DJF season at 6K cools land faster, resulting in divergence and enhanced export of moisture to areas over the ocean near the major landmasses [Liu *et al.*, 2004; Clement *et al.*, 2004; Zhao *et al.*, 2005].

[15] These model results suggest that Borneo’s unique hydroclimatic history could partially reflect the fact that the island is a large enough landmass to respond to temperature-driven changes in seasonal convection in-phase with the other landmasses in the IPWP. However, if the JJA season dominated annual-mean $\delta^{18}\text{O}_p$ at Borneo (as it arguably did

on mainland Asia) [Wang *et al.*, 2005], we might expect that Borneo $\delta^{18}\text{O}$ would show peak depletion near 11–9 ka, when orbital configuration results in perihelion during JJA. Yet both the proxy $\delta^{18}\text{O}$ and simulated $\delta^{18}\text{O}$ from GISS ModelE-R suggest maximum depletion at 4K and not 9K. The 4 ka minimum may reflect a direct influence of increased insolation during the SON season (orbital configuration puts perihelion near SON at 4 ka), as Partin *et al.* [2007] hypothesized. Here we explicitly test that hypothesis by comparing the 9K and 4K results from the GISS ModelE-R timeslice experiments. We find that indeed, precipitation amount is somewhat reduced over Borneo at 9K relative to 4K in the GISS ModelE-R simulations and that the isotopic composition of rainfall is enriched by ca. 1‰ (Figure 7). The latter anomaly is in excellent agreement with the proxy data (Figure 4), but is larger than expected from the amount effect alone, implying less rain derived from the remote southeasterly source and possibly weaker convection at 9K relative to 4K. However, there is no indication that the drying over Borneo at 9K relative to 4K during SON was caused by cooling associated with the change in seasonal insolation; there is a negligible anomaly in surface air temperature ($\Delta\text{SAT } 9\text{K} - 4\text{K} = -0.02^\circ\text{C}$).

[16] Alternatively, we argue that the timing of peak depletion in $\delta^{18}\text{O}$ at Borneo at 4K can be explained in part by large-scale changes in Walker circulation across the Indian Ocean basin. In the 6K PMIP2 simulations, there is a zonal redistribution of precipitation across the Indian Ocean basin during SON, with an increase in precipitation over the western Indian Ocean and a decrease over the eastern Indian Ocean off of Sumatra (Figure 6). This anomaly and the mechanisms that cause it have been discussed in the literature previously [Zhao *et al.*, 2005; Tierney *et al.*, 2011]. Tierney *et al.* [2011] argued that the change in convection is a seasonally lagged effect of Indian monsoon circulation on the western Indian Ocean heat budget. In JJA, the Indian monsoon winds are shifted northward during the early to mid-Holocene, reducing latent heat export out of the western Indian Ocean. This feeds the development of a warm SST anomaly several months later, which triggers an atmospheric response resulting in increased convection and rainfall in the western Indian Ocean, at the expense of divergence and drying in the eastern Indian Ocean in the ascending branch of the Walker cell. The effect of this mechanism on the hydrological cycle in the Indian Ocean is large and robustly simulated by different models (Figure 6). The zonal pattern of anomalies in precipitation and the isotopes of precipitation at 9K relative to 4K in GISS ModelE-R suggests that this mechanism is stronger in the early Holocene than at 4 ka (Figure 7), as might be expected as it is related to the position and strength of the Indian monsoonal winds during boreal summer (which are stronger/farther north at 9K). Upper-level (250 mb) zonal westerly anomalies between 9K and 4K (0.9 m/s) and easterly zonal surface wind anomalies (-0.6 m/s) further suggest that there is a relative weakening in Indian Ocean Walker circulation at 9K during SON.

[17] Given these results, we hypothesize that the observed trend in Borneo hydroclimate across the Holocene reflects a balance between two competing mechanisms: the direct effect that JJA perihelion has on precipitation due to heating and convection, and the indirect effect that JJA perihelion

has on coupled ocean-atmosphere dynamics during SON. In the early Holocene, the latter mechanism dominates, whereas in the mid-Holocene, the former mechanism dominates, resulting in maximum isotopic depletion at a point of compromise around 4 ka. Both of these mechanisms are less important for hydroclimate at Flores and Sulawesi, which do not experience increased precipitation during JJA (Figure 6), and – if the GISS results are a robust indication – sit outside the core of the isotopic anomaly associated with weaker Indian Walker circulation (Figure 7).

4. Conclusions

[18] Our investigation of model and proxy evidence for changes in IPWP hydroclimate during the Holocene reveals that IPWP response to orbitally induced changes in insolation is heterogenous across the region on the seasonal level, and thus differences in hydroclimatic evolution between Borneo and central Indonesia are expected. The Sulawesi site in particular sits near the zero line of most of the seasonal anomalies (Figure 6) and so the new proxy δD_{wax} data we present here – which imply little change in mean δD of precipitation across the Holocene – are in good agreement with the model simulations. As temperature changes complicate the interpretation of Flores calcite $\delta^{18}O$, we cannot robustly determine whether the model simulations agree with the proxy data. At Borneo, we find excellent agreement between the $\delta^{18}O$ proxy data and simulated SON $\delta^{18}O$ of precipitation in GISS ModelE-R, and the Borneo site is uniquely sensitive to large-scale changes in IPWP hydrology that occur during this season. The development of longer proxy isotopic records from Borneo and the vicinity will be an important test of our hypothesis that two competing mechanisms – both related to Indian Ocean atmospheric circulation – influence Borneo hydroclimate on precessional timescales.

[19] **Acknowledgments.** We would like to thank T. Koutavas, E. Schefuß, and two anonymous reviewers for discussion and comments that have greatly improved the manuscript. We thank R. Taroza at Brown University for assistance with the δD_{wax} analyses. We thank the climate modeling groups participating in PMIP2 for providing their data for this analysis, and the PMIP2 Data Archive (supported by CEA, CNRS, and PNEDC) for distributing the data. The analyses were performed using version 02-08-2012 of the PMIP2 database. J. Tierney acknowledges the NOAA Climate and Global Change Postdoctoral Fellowship for support.
