Abstract

Persistent elevation of inflammatory markers such as C-reactive protein (CRP) is associated with increased risk of recurrent cardiac events after acute coronary syndromes (ACS). There is conflicting evidence as to whether aspirin can reduce CRP after ACS. We investigated whether dosage and adherence to aspirin was associated with CRP 3 months after ACS. Adherence to aspirin was monitored using an electronic chip stored in a pill bottle cap for 3 months in a cohort of 105 patients enrolled within one week of an ACS. CRP was measured at baseline and 3 months. Logistic regression was used to test whether poor adherence to aspirin and lower aspirin dosage were associated with increased CRP levels, controlling for age, ACS type, disease comorbidity, baseline CRP, use of clopidogrel and statins, depressive symptoms, smoking, and adherence to other medications. Aspirin adherence was inversely correlated with CRP at 3 months (Spearman's $r = -0.36$, $p < .001$). In the adjusted model, every 10% decrease in aspirin adherence was associated with 1.7 (95% CI 1.2–2.4) increased odds of CRP ≥ 3.0 mg/l at 3 months; and low-dose aspirin was associated with 7.1 (95% CI 1.5 – 33.3) increased odds of CRP ≥ 3.0 mg/l. Charlson comorbidity index, depressive symptoms, and baseline CRP were also predictive of CRP ≥ 3.0 mg/l at 3 months. The association between aspirin adherence and CRP was not attenuated by controlling for other risk reducing behaviors. In conclusion, there is a strong association between aspirin adherence and CRP post-ACS.

Background

The amount of exposure to aspirin may be associated with C-reactive protein (CRP) levels after acute coronary syndromes (ACS).^{1–6} Accordingly, we tested whether lower adherence to aspirin and/or lower prescribed aspirin dosage in the 3 months after hospitalization for an ACS were associated with higher CRP levels at 3 months. Aspirin adherence was assessed using an electronic medication monitor. As adherence to aspirin may be a proxy for adherence to other medications that are more definitively linked with anti-inflammatory effects, we also explored the association between aspirin adherence and CRP level after controlling for self-reported adherence to medications in general.

Methods

This study was performed as part of the Coronary Psychosocial Evaluation Study (COPES), a series of multi-site observational cohort studies that examine the relationship between depression and prognosis after ACS.⁷ Briefly, between May 1, 2003 and April 15, 2005, a cohort of patients was recruited from 3 academic hospitals (Yale-New Haven Hospital and Hospital of St. Raphael in New Haven CT; Mount Sinai Medical Center in New York City) within 1 week of hospitalization for an ACS. The study defined ACS as either acute myocardial infarction (MI) or unstable angina using standard criteria⁸, and required patients to have symptoms consistent with acute myocardial ischemia and at least 1 of the following: ischemic electrocardiographic changes, angiogram indicative of coronary artery disease on current admission, documented history of coronary artery disease, or acute rise in serum troponin levels above the laboratory cutoff of each hospital. A study cardiologist confirmed ACS eligibility for all patients. An additional eligibility criteria was a score on the Beck Depression Inventory (BDI) of ≤ 4 or ≥ 10 , ranges selected in the parent study to delineate non-depressed and depressed patients at baseline. Patients were excluded if they lived in a nursing home, exhibited cognitive impairment, or engaged in alcohol or substance abuse. All patients gave informed consent prior to enrollment. The study was approved by the Institutional Review Boards at each hospital.

Upon hospital discharge, patients who were prescribed a daily dose of aspirin (81mg, 162mg, or 325mg) and who were willing to have their aspirin adherence monitored by an electronic chip in the cap of their pill bottle were provided with a 90-day supply of their prescribed aspirin in a MEMS (Medication Event Monitoring System; APREX Corp, Fremont, CA) bottle. The MEMS device records the date and time whenever the bottle cap is opened. MEMS data were collected continuously over the next 3 months. The percentage of days the bottle cap was opened the correct number of times (once a day) was calculated.

Patients also provided blood samples in hospital and after 3 months for measurement of CRP. After centrifugation, serum samples were stored in aliquot portions at -70°C . Samples were shipped to a core laboratory (Specialty Laboratories, Valencia, California, USA) for analysis of high sensitivity CRP concentrations. The limit of detection of the CRP assay was 0.01 mg/L; the analytical measurable range was 0.2–160 mg/L; and the inter- and intra-assay coefficient of variation was $<8\%$. Concentrations were determined by turbidimetry (Bayer Diagnostics, Leverkusen, Germany).

One hundred seventy-two patients agreed to have their adherence monitored using MEMS. Details regarding enrollment into this substudy have been described elsewhere.⁹ One hundred and five of these patients (61%) had blood samples drawn at baseline and 3 months. Patients who refused the blood draw did not significantly differ ($p > 0.20$) from patients who agreed with respect to sociodemographics, depression score, and clinical factors. A CRP of

≥ 3 mg/l was defined as elevated, as this identifies increased risk for recurrent events and death.

Baseline demographics, discharge medications, and clinical variables, including the constituents of the Charlson comorbidity index, a validated measure of risk for death in patients with chronic illness,¹⁰ were obtained by patient interview and chart abstraction at the time of enrollment. Participants completed the BDI, a validated self-report instrument that has been used in prior studies of depression and ACS, and that predicts post-ACS event-free survival.¹¹

At 3 month follow-up, patients returned the MEMS cap and were asked about their adherence to cardiovascular risk lowering behaviors, included whether they had (1) smoked tobacco products in the last 7 days; (2) participated in a cardiac rehabilitation program; (3) exercised regularly; and/or (4) modified their diet to be heart healthy. In addition, patients were asked about their adherence to their medications using the Morisky scale; a self-report tool that has good agreement with objective measures of medication adherence.¹² The scale is comprised of 4 items, each of which is scored as either 0 (adherent) or 1 (non-adherent). Total score is calculated by summation to obtain a total score between 0 and 4. Patients with a score from 0 to 1 were categorized as having good medication adherence, whereas patients with a score from 2 to 4 were categorized as having poor medication adherence.

CRP was log transformed so that it was normally distributed. Spearman's correlation was used to assess the association between monitored aspirin adherence and CRP at 3-months. Chi square and t-tests were used to compare differences in patient characteristics between patients with and without elevated CRP, using a cutoff of 3mg/l. Logistic regression was then used to determine whether adherence to aspirin and aspirin dosage were independently associated with CRP level (≥ 3 mg/l versus < 3 mg/l). Using linear regression, we also tested whether aspirin dosage and aspirin adherence were independently associated with a continuous measure of CRP. Models were adjusted for age¹³; ACS type¹⁴ (UA versus MI); Charlson Comorbidity index¹⁰; baseline CRP; statin and plavix use; smoking status¹⁵; and depressive symptom severity (BDI score) at baseline.^{16,17} Analyses were also adjusted for self-reported adherence to overall medications as measured by the Morisky scale.¹² The *a priori* choice of predictors was based on a review of the literature for important factors that may be associated with CRP after ACS. Finally, we used t-tests to determine whether adherence to aspirin was associated with aspirin dosage (81mg versus 162mg or 325mg) and with self-reported exercise, following a heart healthy diet, and attending cardiac rehabilitation. All statistical analyses were performed using SPSS 13 (Chicago, Inc.).

Results

Baseline and 3-month blood samples and MEMS-assessed aspirin adherence were available for 105 patients. The mean age of this sample was 59 (range 25–83), 47% were women, 87% were Caucasian, and 6% self-identified as Hispanic. The index ACS event was ST elevation MI for 24% of patients, non-ST elevation MI for 30% of patients, and unstable angina for 47% of patients. The mean adherence to aspirin (% days aspirin taken correctly) was 87%, (range 23%–100%), and 24% of patients took their aspirin on $< 80\%$ of days monitored.

Compared to patients with lower CRP level (< 3 mg/l), patients with higher CRP level (> 3 mg/l) at 3 months were more likely ($p < .05$) to have higher baseline Charlson comorbidity and BDI depressive symptom scores; and to have higher baseline CRP (Table 1). In contrast, patients with higher CRP level at 3 months were less likely to be discharged

on clopidogrel or statins, though these differences were only statistically significant for statins.

Twenty-one patients (20%) were discharged on low dose aspirin (81 mg daily), and 83 patients (79%) were discharged on high dose aspirin (325mg daily). One patient was discharged on 162mg daily and was included in the high dose group. A greater proportion of patients hospitalized for MI were prescribed high dose aspirin at discharge as compared to patients hospitalized for UA (92% vs 67%, respectively, $p=.002$). Patients discharged on low dose aspirin had significantly higher CRP at 3 months than patients prescribed high dose aspirin even though low dose aspirin patients had lower CRP at baseline (Figure 1). In an adjusted analysis, low dose aspirin was associated with 7.1 (95%CI 1.5 – 33.3) increased odds of CRP ≥ 3.0 mg/l at 3 months (Table 2). Aspirin adherence did not significantly differ between patients prescribed low versus high dose aspirin.

There was a dose-response relationship between increasing level of aspirin adherence and decreasing CRP concentration at 3 months (Figure 2). Adherence to aspirin by MEMS over 3 months was inversely correlated with CRP at 3 months (Spearman's $r = -0.36$, $p<.001$). In an adjusted model, aspirin adherence was a significant predictor of CRP (Table 2); for every 10 percent decrease in aspirin adherence, the odds of elevated CRP level at 3 months increased by 1.7-fold (95% CI 1.2 – 2.4). Higher Charlson score, baseline depressive symptom severity, baseline CRP, and lower aspirin dosage also predicted elevated CRP levels in this model.

Setting a cut-off for poor adherence to aspirin at less than 80%, a greater proportion of patients with poor adherence had elevated CRP at 3 months than patients with good adherence (79.2% vs. 33.3%, $p<.001$). In the adjusted model controlling for the same factors, patients with poor adherence to aspirin had 7.6 (95% CI 1.9 – 30.3) greater odds of having an elevated CRP level at 3 months. Using continuous (log transformed) CRP scores as the outcome, instead of a categorical CRP cut-off, did not substantially alter the association between aspirin adherence and CRP. However, Charlson score and aspirin dosage were no longer significant predictors of CRP elevation in this linear regression model (data not shown).

Aspirin adherence was not associated with self-reports of adhering to a heart healthy diet ($p=0.74$) or attending cardiac rehabilitation ($p=0.93$). There was, however, a significant correlation between adherence to aspirin by MEMS and adherence to overall medications as measured by the self-report Morisky scale (Spearman's $r=.29$, $p=.003$). Aspirin adherence was also higher among patients who self-reported not smoking and exercising regularly ($p = 0.03$ and 0.03 , respectively). Controlling for these behaviors did not significantly change the strength of the association between aspirin adherence and CRP at 3 months.

Discussion

The current analyses demonstrate a strong, independent association between adherence to aspirin and CRP in the first 3 months after ACS. This supports the hypothesis that aspirin has direct anti-inflammatory effects, separate from its anti-platelet effects, and that these anti-inflammatory effects are maximized with optimum adherence to aspirin. The plausibility of an anti-inflammatory effect from aspirin is supported by preclinical data showing that aspirin may have inhibitory effects on the activity of nuclear factors required for the expression of genes encoding pro-inflammatory molecules.^{18,19} The likelihood that aspirin has direct anti-inflammatory effects is further supported by our data showing an association between higher aspirin dosage and lower CRP at 3 months. The optimal dose of

aspirin after ACS remains unclear²⁰; these data suggest there may be a biological rationale for using high dose aspirin.

An alternative explanation for the strong relationship between aspirin adherence and CRP is that adherence to aspirin may be representative of medication adherence more broadly, or to adherence with a range of risk reducing behaviors associated with lower CRP levels in other studies.²¹ We tested for this possibility by comparing electronically-monitored aspirin adherence with self-reported adherence to overall medications and other heart healthy behaviors. We found a weak correlation between electronically-monitored adherence to aspirin and self-reported adherence to medications. This is consistent with research showing that adherence to one medication does not necessarily correlate closely with adherence overall.²² A direct test of this explanation, however, would require objective adherence monitoring to either the full range of medications prescribed post-ACS, or specifically to those medications with known anti-inflammatory effects. There were significant associations between aspirin adherence and self-reported smoking and exercising at 3 months; yet, analyses adjusting for these behaviors did not substantially alter the association between aspirin adherence and CRP level. This strengthens the likelihood that aspirin directly mediates CRP levels.

Another interesting finding is that depression was associated with elevated CRP even after adjusting for aspirin adherence and medical comorbidity. This supports our earlier finding that patients with persistent depression 3 months after ACS were more likely to have persistently elevated CRP.¹⁷ The prognostic risk conferred by depression after ACS is well documented, but the cause of this increased risk remains uncertain.^{23,24} These data support an association between depression and increased inflammation that is, at least in part, independent of the influence that depression has on medication adherence.^{25,26}

We did not find a significant association between being discharged on statin or clopidogrel and 3 month CRP level. Our study may have been underpowered to find statistical differences in these relationships. Alternatively, being discharged on these medications may not be representative of actually taking them. It is possible that patients discontinued or poorly adhered to these medications after discharge, effectively weakening the association between being discharged on these medications and CRP. A direct test of this explanation, however, would require objectively monitoring adherence to these medications.

There were several important limitations to our findings. First, the sample was relatively small, resulting in wide confidence intervals for some predictors of elevated CRP. Recruitment procedures could have led to a bias in the recruitment of subjects. The lack of an objective measure of adherence to other potentially important anti-inflammatory medications such as statins increases the possibility of confounding by adherence to these medications. Similarly, the assessment of health behaviors such as exercise was not obtained using objective tools.

Despite these limitations, we found a robust association between aspirin adherence in the first 3 months after ACS and CRP, even after controlling for multiple potential confounders. Whether this relationship is mediated directly through the biological activity of aspirin or whether it is an exemplar of broader adherence to prescribed medications and behaviors that reduce inflammation, the data illustrate the biological impact of poor adherence on inflammation. Poor adherence to medications is common in patients with cardiovascular disease²⁷, and has been associated with recurrent cardiovascular events.²⁸ Medication adherence is a potentially modifiable behavior that should be closely monitored in post-ACS patients. Future studies investigating the anti-inflammatory effects of aspirin or other drugs in post-ACS patients should include an assessment of medication adherence.

Figure 1.

Relation of aspirin dose and C-reactive protein (CRP) concentration during hospitalization for an acute coronary syndrome and 3 months later. Patients prescribed low-dose aspirin (81 mg) had higher overall CRP concentrations at 3 months as compared to patients prescribed high-dose aspirin (162 mg or 325 mg).

Abbreviations: CRP, C-reactive protein; ASA, aspirin

* $p = 0.42$

** $p = 0.02$

Figure 2.

Relation of mean aspirin adherence and C-reactive protein concentration 3 months after an acute coronary syndrome. There is a dose response relationship between aspirin adherence and CRP concentration with increasing adherence associated with decreasing CRP at 3 months.

Abbreviation: CRP, C-reactive protein

Table 1

Baseline characteristics according to C-reactive protein level 3 months after acute coronary syndrome*

Characteristic	CRP ≤ 3 mg/l (N=59)	CRP > 3 mg/ (N=46)	p-value
Age, mean (SD), (years)	58.2 (11.4)	60.8 (13.2)	0.28
ACS type, myocardial infarction	35 (59%)	21 (46%)	0.16
Charlson comorbidity index, mean (SD)	0.7 (0.9)	1.7 (1.7)	<.001
BDI baseline, mean (SD)	5.6 (6.2)	11.3 (8.7)	<.001
CRP baseline, mean (SD)	13.8 (18.4)	25.0 (23.3)	0.01
Smoking at 3 months	8 (14%)	7 (15%)	0.81
Discharged on statin	55 (93%)	36 (78%)	0.03
Discharged on clopidogrel	52 (88%)	35 (76%)	0.10
Good adherence to overall medications	49 (83%)	36 (78%)	0.54
Prescribed low dose aspirin (81 mg)	7 (12%)	14 (30%)	0.02
Aspirin adherence 0–3mo, mean (SD)	91.6 (13.3)	80.8 (17.9)	0.001

* Abbreviations: CRP, C-reactive protein; ACS, acute coronary syndrome; BDI, Beck Depression Inventory score

Table 2

Unadjusted and adjusted* odds ratios for predictors of elevated C-reactive protein level (CRP >3 mg/l) 3 months after acute coronary syndrome[†]

Predictor	Unadjusted OR (95% CI)	Adjusted OR (95% CI)
Age	1.02 (0.99 – 1.05)	0.98 (0.93 – 1.04)
CRP concentration at baseline [‡]	1.03 (1.01 – 1.05)	1.04 (1.01 – 1.07)
ACS type, myocardial infarction	0.58 (0.26 – 1.26)	1.08 (0.29 – 4.01)
Charlson comorbidity index [‡]	1.99 (1.32 – 2.99)	1.96 (1.12 – 3.41)
Discharged on statin	0.26 (0.08 – 0.90)	0.32 (0.05 – 2.02)
Discharged on clopidogrel	0.43 (0.15 – 1.21)	0.99 (0.16 – 6.21)
Smoker at 3 months	1.14 (0.38 – 3.43)	0.68 (0.14 – 3.42)
BDI score at baseline [‡]	1.11 (1.05 – 1.18)	1.16 (1.07 – 1.26)
Poor adherence to medications overall (Morisky score)	1.36 (0.51 – 3.61)	0.97 (0.15 – 6.37)
Prescribed low dose aspirin (81 mg) at discharge [‡]	3.22 (1.19 – 9.09)	7.14 (1.54 – 33.33)
Poor adherence to aspirin [‡] (continuous per 10 percent decrease)	1.65 (1.20 – 2.27)	1.65 (1.15 – 2.35)

* Model adjusted for age, C-reactive protein at baseline, type of acute coronary syndrome (unstable angina is the reference group), comorbidity (Charlson score), smoking status at three months, discharge medications (statin, clopidogrel), depressive symptom severity (BDI score), adherence to medications (Morisky score), and aspirin dosage (high dose aspirin 162 mg or 325 mg is the reference group)
